A new method of testing the effect of industrial chemicals (2-3 mg/kg) on DNA synthesis in mouse spermatogonia, especially the dynamics of DNA breakdown, has been developed. Progression of DNA breakdown in spermatogonia can be divided into two stages: the beginning of DNA breakdown and the accumulation of single strand breaks (SSBs). In the experiments, two effects of low-dose ethyl-fluoride on male mice have been studied: inhibition of spermatogonial proliferation in different periods of the spermatogenesis as well as a progressive accumulation of SSBs during DNA breakdown in late spermatids. The results obtained show that the dose of 3 mg/kg does not cause significant changes in DNA synthesis and DNA breakage. At the same time, the dose of 30 mg/kg causes a statistically significant inhibition of spermatogonial proliferation in both stages of the spermatogenesis. The dose of 300 mg/kg is cytotoxic, causes DNA breakdown in spermatids, and does not significantly affect the DNA synthesis in spermatogonia. It is shown that ethyl-fluoride inhibits the DNA synthesis and breakdown in spermatids at a dose of 30 mg/kg. The brain is one of the most energy-consuming organs in the human body and, therefore, various strategies are undertaken to maintain its functional integrity and minimize the impact of the energy-demanding process of learning and memory encoding. Adenosine, a major constituent of neural extracellular fluid, has been proposed to act as a "brake" that offsets the effect of neuronal excitation. However, the recent findings are clearly showing that adenosine, through its stimulation of A2 adenosine receptors (

New research into the effect of sea level rise on coral reefs has shown that some species can not only recover from bleaching, but even get bigger. The research, published in Science, looked at five species of reef-building coral, and found that all of them had managed to recover from mass bleaching from a tropical storm that occurred in 1999, allowing them to grow larger than they did before the storm. The research was done by a team of researchers from the University of British Columbia and Lund University in Sweden, led by UBC's Alison Lough, a UBC research associate professor in the department of earth and ocean sciences. "These are the first controlled experiments that have shown that marine corals can re-grow in such harsh conditions," said Lough. "It was a bit of a shock to us," said Lough. "What we did see is that the corals made a lot of new skeletons. But not all the corals grew back the same, and this was a surprise. We found that some of the corals grew back bigger than the corals prior to the storm." The experiments looked at five species of coral, all of which can form large colonies on the ocean floor. The researchers, who worked in a lab where they could adjust the water quality, exposed the coral to three levels of a natural bleaching event. In a first experiment, bleaching conditions were set up by exposing the colonies to a mild level of warming. Then, in a "supersaturation" experiment, they exposed the corals to more extreme levels of warming than normally occur. The last experiment, the "supersaturating" and "severe" experiment, involved exposing the corals to a mild level of warming mixed with a heavy dose of a toxic substance that causes stress. "The corals had to deal with all of these stresses at once," said Lough. "The whole experiment was over four weeks." The researchers found that: – In the mild and supersaturated experiments 3da54e8ca3
